COVID-19 progresses with a heterogeneous clinical course that is mild to moderate in most cases, and severe in approximately 10–15% of patients.

Patients with comorbidities (diabetes mellitus, hypertension, heart disease, obesity, and immunosuppression), in general elderly, can evolve with higher frequency to severe cases of the disease, with severe respiratory failure, requiring intensive care in most cases.

As yet, there is no specific therapy for covid-19. Thus, as an alternative, there is the transfusion of plasma obtained from individuals who are convalescent from covid-19, referred to as convalescent plasma (CP), which contains neutralizing antibodies against SARS-CoV-2 virus.1

The use of CP seeks to passively transfer antibodies to the patient until the affected organism has the time to mount their own immune response.

Observational studies and controlled studies, suggest that CP can be useful, especially units which contain high-titer...
neutralizing antibodies, with patients presenting a better clinical course.\textsuperscript{2,3}

Recent publications have shown better results with the use of CP in the early days of symptom onset, up to 72 h, before clinical worsening has occurred, as late transfusion seems not to provide clinical benefits.\textsuperscript{4,5}

Most studies used a single dose of PC, ranging from 200 to 500 mL, infused over one or more days.

Altogether, those studies suggest that CP transfusion, containing high-titer neutralizing antibodies, can be of clinical benefit, for specific groups of patients, if administered early.

Potential risks associated with PC transfusion are no greater than those of plasma use in other situations.\textsuperscript{6} It is worth mentioning, in specific ways, the possibility of circulatory overload risk, especially in elderly patients and in those with renal failure or heart disease, who are less able to tolerate sudden increase in circulating volume and TRALI. For the latter situation, it is considered prudent to use plasma from nulliparous donors, or from donors who had not previously received a hemocomponent transfusion.

Finally, it is determined that the collected CP units contain adequate levels of neutralizing anti-SARS-CoV-2 antibodies. The ideal test for determining these titers is the neutralizing antibody activity test.\textsuperscript{7} However, this test is labor-intensive, hard-to-perform and scarcely available, and requires a level III biosafety laboratory.

There have been some studies reporting satisfactory results with results obtained by traditional enzyme immunoassay methods, such as Elisa and chemiluminescence, where the intensity of the reading (OD) seems to correlate well with neutralizing antibody titers\textsuperscript{3,7} (Table 1).

In summary, consider using CP, in patients with COVID-19, in the situations and ways described below:

1. Immunosuppressed patients (especially those treated with anti-CD20 monoclonal antibodies).
2. Elderly patients (\textgeq 60 years old).
3. Patients with comorbidities: diabetes mellitus, hypertension, coronary heart disease and obesity.
4. CP with high-titer neutralizing antibodies (\textgeq 80), or high DO.
5. Within 72 h of symptom onset.
